SLOPE STABILITY STUDIES, 1963

by<br>K. Van Dalen

Internal Report No. 306
of the
Division of Building Research

OTTAWA

## PREFACE

The interpretation of shear strength parameters from labor atory tests on the sensitive Leda clays of Eastern Canada is controversial. It is necessary, therefore, to evaluate the laboratory results by field observations. Several specific stability analyses have been carried out for this purpose.

During the summer of 1963, Professor K. Van Dalen of Carleton University, who was with DBR/NRC as a guest worker, was engaged in a preliminary study of slopes over a broad area of the Ottawa region. The first stage of this work was to identify the largest slopes from aerial photographs of the region. Approximate cross-sections were drawn using stereo pairs and some of these were checked by stadia surveying.

Effective stress stability analyses of these selected slopes were made using tabulated stability coefficients. A more refined analysis by the method of slices was made on some of the slopes. This report was prepared as a basis for further study of the problem by more refined field observations and computer analyses.

Ottawa
January 1965
R. F. Legget

Director
by

K. Van Dalen

The mobilized shearing resistance of a natural soil may be assessed by analysing the stability of natural slopes. For such a study of the Leda clay, the steepest slopes existing within a limited area near Ottawa were selected from aerial photographs. Profiles were drawn using stereo-photos and some of these were checked on the ground by engineering levelling. Assuming that the steepest slope is at limiting equilibrium, values of $c^{\prime}$ and $\phi^{\prime}$ (cohesion and friction angle in terms of effective stresses) can be determined by stability analyses.

The stability analysis of a slope, assuming the factor of safety, $F=1.0$ and an appropriate value of $\phi^{\prime}$, would give the value of $c^{\prime}$ which is being mobilized in order to maintain equilibrium. If the slope is on the point of failure the soil has no reserve of cohesion left to be mobilized; $F$ is in fact equal to 1.0 , and the value of $c^{\prime}$ found in the stability analysis is the maximum of which the soil is capable. This value of $c^{\prime}$ is the cohesive strength of the soil.

If it were possible to find a slope whose $F$ was 1.0 , it would be a simple matter to find the cohesive strength of the soil. It is not easy to determine which, if any, of the many slopes within a region have an $F$ of 1.0 . The approach used was to measure as many slopes as seemed at all significant within an area. A crude stability analysis was performed on each slope, assuming $F=1.0$ and determining $c^{\prime}$. In most of the slopes $F$ will be greater than 1.0 and thus $c^{\prime}$, the cohesion mobilized, will be less than the cohesive strength of the soil. The slope within any small region which gives the highest value of $c^{\prime}$ will be (assuming that the soil properties do not change) the slope with an actual factor of safety closest to 1.0 . If slides have occurred immediately adjacent to this slope, one may infer that not only is this slope the one having an F nearest to 1.0 within the region, but further that this factor of safety is approximately equal to 1.0 . Thus, the value of $c^{\prime}$ found from this slope is not only the value of mobilized cohesion nearest to the cohesive strength of the soil, it is in fact approximately equal to the cohesive strength. In this manner, a good estimate (erring on the conservative side if the slope is still standing) of the cohesive strength of the soil in the region may be made.

## SCOPE OF WORK

Three areas within the Ottawa district were selected for investigation. These areas were Green Creek - Mud Creek, Breckenridge, and Clarence Creek. The locations of the Green Creek Mud Creek and Breckenridge areas are shown in Figure l, and the locations of slope profiles which were studied in detail are shown in Figures 2 and 3. The Clarence Creek region (not shown) is about 30 miles east of Green Creek. The Green Creek - Mud Creek region appeared to be a youthful region; although steep banks were present, there had not been any major slides. The Green Creek landslide is of course the notable exception, but this slide did not occur in the banks of the creek where the steep slopes exist. The Breckenridge area appeared to be a somewhat more-advanced landslide area. Numerous scars of ancient slides were visible - these still remain, however, as steep banks which give rise to moderately large earth flows as evidenced by the recent Breckenridge slide. The third area, surrounding Clarence Creek, appeared to be a well-developed slide area. The area was completely covered by scars of ancient landslides. It was given only a cursory inspection, but few banks of any magnitude were observed and there has been no evidence of any recent movement of the land.

The areas have been adequately documented by moderately low level ( 6,000 to 9,000 feet) aerial photographs. It was decided, therefore, to use photogrammetric methods to measure the profiles of significant slopes. Measurements were performed using a "Santoni" stereo plotter. The instrument is convenient to use although it was found that a period of time was required to train the operator's eyes to fuse the measuring marks. The machine is particularly suited to the scanning of a stereo pair because of its ease of horizontal movement in X and Y directions. Elevations could be measured to an average accuracy of about $\pm 4$ feet from photos taken from 6, 000 ft . In a number of instances, however, larger errors were present. This may have been due to tip or tilt of the photographs for which no correction was made. The accuracy of the photogrammetric measurements could therefore have been improved, but it was thought that allowance for tip and tilt was not justified in view of other possible errors.

The cohesion required to give each of the measured slopes an $F$ of 1.0 was conveniently and quickly estimated using stability coefficients given by Bishop and Morgenstern (l). Some rearrangement was necessary as the stability coefficients are set up to facilitate finding $F$ when $c^{\prime}$ is known. The $c^{\prime}$ required for all slopes investigated
with the use of air photos is summarized in Table I. Within each area, two or three slopes giving the highest value of $c^{\prime}$ were selected for a more careful analysis. If the slope was originally measured by photogrammetric means it was checked where possible by a stadia survey. This more-accurate profile was then analysed by Bishop's method of slices to determine the location of the most critical circle, and the cohesion necessary to give stability was computed.

DETAILED SUMMARY OF WORK DONE TO DATE
(1) Number of Slopes Measured

Thirty-two slopes were measured. Of these, 13 were in the Green Creek area, 16 in the Breckenridge area and 3 in the Clarence Creek area. Slopes 1 to 9 were within an area covered by $2 \frac{1}{2}-\mathrm{ft}$ contour maps, as were slopes 31 and 32 . The remainder were initially measured from air photos. Certain slopes were selected as meriting further attention and these slopes, (Nos. 11, 2l, and 27), were checked by stadia. Small earth flows had occurred at the scene of slopes 11 and 21 since the air photographs had been taken, confirming that these slopes were nearing an $F$ of l. 0 . Slope No. 12 was the natural slope existing prior to the Breckenridge slide in May 1963. It could not be checked by stadia, but was drawn as an average of three sets of determinations from the air photos. It is believed to be a good approximation to the slope existing prior to the slide.

## (2) Use of Stability Coefficients

The slopes were analysed initially using the stability coefficients of Bishop and Morgenstern. From Figures 7, 8, 9, 10, 11 and 12 of Bishop and Morgenstern's paper (1), another set of curves was prepared which can be used to give values of $c^{\prime}$. These curves require a value to be chosen for $\phi^{\prime}, r_{u}$ and $\gamma$. With these selected, one enters the appropriate graph with $\beta$ (the slope) and reads the corresponding value of $c^{\prime} / \gamma H$. Cross multiplication gives $c^{\prime}$. Values of $c^{\prime}$ for all slopes investigated are listed in Appendix A.
(3) Choice of Values used for $\gamma, \phi^{\prime}$ and $r_{u}$

The stability coefficients give a rapid method of estimating $c^{\prime}$. A choice of values of $\gamma, \phi^{\prime}$ and $r_{u}$ must be made for use with the stability coefficients.
(i) Choice of y. - A study of records of values of bulk density was made. The records from the Green Creek landslide, HMCS Gloucester, Cumberland and the Sewer Plant were used and $\gamma$ was plotted against depth. The best value of $\gamma$ was chosen to be 100 pcf.
(ii) Choice of $r_{u}$. - No clear evidence was available to indicate the correct value of pore-pressure ratio to be used. It was thought not unreasonable to assume the ground water table (G. W. T.) to reach the surface during times of spring run-off. No seepage was considered and, hence, the pore pressure ratio becomes $r_{u}=\gamma_{w} h_{w} / \gamma_{h}$. If G. W.T. at the surface is considered to hold, then $h_{w}=h, \gamma$ is 100 , and $r_{u}$ becomes 0.624 .
(4) Variation of Parameters

The choice of the values for the parameters was comparatively arbitrary with only slight support from actual observations. Hence, it is useful to determine the sensitivity of the values of $c^{\prime}$ to changes in $\gamma, \phi^{\prime}$, and $r_{u}$. Accordingly, these quantities were varied over what was judged to be the limit of their probable values. Table II indicates the assumed correct value and the range of other values considered.

Because a change in $\gamma$ results in a change in $r_{u}$,
$\left[r_{u}=\gamma_{w} h_{w} / \gamma h\right]$, the values of $r_{u}$ for various bulk density and ground water conditions are given in Table III.

The parameters were varied to give seven possible values of $c^{\prime}$ for each slope. These values may be found in Appendix A. The values of $c^{\prime}$ for each slope using the most probable combination of values of $\gamma, \phi^{\prime}$ and $r_{u}$ have been summarized in Table I. Slope No. 9 is shown in Figure 4 and the effect of variations of $\gamma, \phi^{\prime}$ and $r_{u}$ on the value of $c$ ' for this slope is shown graphically in Figure 5.
(5) Selection of Slopes for More Intensive Study

Within each area several slopes were selected for further study on the basis of their values of $c^{\prime}$ determined using stability coefficients and the most likely values of $\gamma(100), \phi^{\prime}\left(15.0^{\circ}\right)$ and $r_{u}(.624)$. The slopes selected were Nos. $1,2,6,9$ and 11 in the Green Creek area, and Nos. 12, 13, 21 and 27 in the Breckenridge area. These slopes had the highest values of $c$ ' within the region and were thus assumed to be the nearest to mobilization of the full cohesive strength of soil. Of the slopes which were selected,

Nos. 11, 12, 13, 21 and 27 were measured from air photos, and the others were measured from $2 \frac{1}{2}-\mathrm{ft}$ contour maps that were considered to be sufficiently accurate. Slopes 11,21 and 27 were remeasured by stadia. Slopes 11 and 21 showed evidence of further movement since the air photos were made. Slopes 12 and 13 no longer exist since the landslide at Breckenridge but were checked by air photo measurements. There were insufficient slopes measured in the Clarence Creek area to select any significant ones.
(6) Stability Analysis of Selected Slopes Using Method of Slices

The slopes which were selected for more intensive study departed considerably from the straight line slope assumed in Bishop's stability coefficient method. Thus, in order to determine more precisely the value of $c^{\prime}$ required to give stability to these slopes, it is necessary to conduct an analysis using Bishop's method of slices. Only one of the slopes (No. 9, Figure 4) was analysed completely using this method. The value of $c^{\prime}$ for this slope, as determined by the method of slices, was 610 psf. This compares with the value of 549 psf found using stability coefficients.

A second slope (No. 12), was begun, but only 5 circles were drawn and computed. The value of $c^{\prime}$ found from these few circles was 808 psf. This value compared with the $c^{\prime}=760 \mathrm{psf}$ found by use of stability coefficients. More circles should be drawn to confirm the 808 psf value that was obtained.

For slope No. 9 the contours of centres of circles giving equal values of $c^{\prime}$ were slotted. These contours agree in general with the shape of contours for similar quantities reported by Bishop and Morgenstern (1).
